ABSTRACT

Development of Experimental Methods for the Evaluation of Aggregate Resistance to

Polishing, Abrasion, and Breakage. (December 2005)

Enad Muhib Mahmoud, B.S., University of Jordan, Jordan

Chair of Advisory Committee: Dr. Eyad Masad

Aggregate properties influence different aspects of asphalt pavement performance.

Aggregate polishing characteristics are directly related to pavement surface frictional properties and thus to skid resistance. Aggregate resistance to degradation (abrasion and breakage) is another important property that influences pavement performance.

Aggregate degradation could take place during production due to plant operations and during compaction, leading to change in aggregate characteristics and mix properties. In addition, aggregate resistance to degradation is important in mixes such as Stone Matrix Asphalt (SMA) and Open Graded Friction Course (OGFC) that rely on stone-to-stone contacts among coarse aggregates. Some aggregates in these mixes fracture due to the high stresses at contact points.

Many test methods exist for measuring aggregate polishing and degradation, but a critical review of these methods reveals that they suffer from being time consuming, are unable to differentiate between aggregates with distinct resistance to polishing, or unable to differentiate between aggregate resistance to abrasion and breakage. New methodologies are needed to give better assessment of aggregate resistance to polishing, abrasion, and breakage.

The thesis presents the development of new methods for measuring aggregate resistance to polishing, abrasion, and breakage. These methods rely on measurements using the Aggregate Imaging System (AIMS) and Micro-Deval. The new method for measuring aggregate resistance to polishing monitors change in aggregate texture as a function of polishing time. As such, it provides the initial texture, rate of polishing, and final texture. The new method for measuring aggregate degradation is capable of distinguishing between breakage and abrasion. In this method, abrasion is defined as the reduction in aggregate angularity, while breakage is defined by fracture of particles. The new methods are shown to be rapid and accurate, and they require reasonable training.

Since both AIMS and Micro-Deval are used in the new methods, it was necessary to evaluate the repeatability of these two methods. Measurements using two AIMS units and two Micro-Deval machines were used to assess the variability. There was no statistical difference between the measurements of the two AIMS units or between the measurements of the two Micro-Deval units.

DEDICATION

This thesis is dedicated to my mother and to my father.

ACKNOWLEDGMENTS

I would like to express my special thanks to Dr. Eyad Masad, for his guidance, encouragement, patience, and support throughout my study.

I would like to thank Dr. Amy Epps Martin and Dr. Cliff Spiegelman for serving as members of my graduate committee.

I would like to thank the Texas Department of Transportation (TxDOT) for providing the funds for this research. Also I would like to thank Mr. Edward Morgan and Mr. Michael Dawidczik from TxDOT for their help in providing the samples and conducting tests at TxDOT labs for this research. Special thanks go to Shadi Saadeh and Osama Awwad for their encouragement throughout my study at Texas A&M University. Also, I would like to thank Anthony Luce and James Patrick Miles II for their tremendous help in testing, data collecting, and traveling. Finally, I thank all my friends in Jordan for there support all the time.

CHAPTER I

INTRODUCTION

PROBLEM STATEMENT

Aggregate properties influence several aspects of asphalt pavement performance.

Angular and textured aggregates are desirable to improve aggregate resistance to permanent deformation. Aggregate polishing characteristics affect asphalt pavement microtexture, and consequently, affect pavement surface frictional properties.

Aggregate resistance to degradation (abrasion and breakage) is also an important property that influences performance. Abrasion is defined as the loss of aggregate surface angularity, while breakage refers to fracture of particles. Some aggregates experience significant abrasion and breakage during plant operations and compaction, leading to changes in aggregate characteristics critical to Hot Mix Asphalt (HMA) design. Consequently, HMA characteristics in the field would deviate from the designed mix.

New generation mixes such as Open Graded Friction Course (OGFC) and Stone Matrix Asphalt (SMA) rely on stone-to-stone contacts among coarse aggregates to sustain traffic loads. The stress transfer mechanisms in these mixes bear high contact stresses at the contact points, which could cause aggregate degradation at the contact points.

This thesis follows the style and format of *Journal of Materials in Civil Engineering* (ASCE).

Recent studies at Texas A&M University have focused on developing imaging methods or characterizing aggregate shape characteristics and their influence on HMA performance. This study focuses on developing new test methods for quantifying aggregate resistance to polishing and degradation (abrasion and breakage).

Many test methods exist for measuring aggregate polishing and degradation. However, a critical review of these methods reveals that they suffer from being time consuming, unable to differentiate between aggregates with distinct resistance to polishing, or unable to differentiate between aggregate resistance to abrasion and breakage. For example, the Micro-Deval is repeatable in measuring aggregate degradation, but it is not able to differentiate between aggregate breakage and abrasion. The new methodologies that were developed in this study rely on the Aggregate Imaging System (AIMS) and Micro-Deval measurements to quantify aggregate resistance to polishing and degradation. As part of this study, measurements conducted using two AIMS units and two Micro-Deval machines were analyzed to establish the reproducibility of these two methods using a wide range of aggregates.

OBJECTIVES OF THE STUDY

This study has two main objectives:

- Development of new experimental methods to measure aggregate resistance to polishing, abrasion, and breakage using the Aggregate Imaging System (AIMS) and Micro-Deval machine; and

- Assessment of the variability in the Micro-Deval and AIMS measurements conducted in two different laboratories.

THESIS ORGANIZATION

This thesis is organized in five chapters as follows:

- Chapter I introduces the main motivation of this study, followed by the objectives and the outline of the thesis.
- Chapter II contains a literature review that emphasizes the significance of aggregate resistance to polishing, abrasion, and breakage in asphalt pavement performance. In addition, the literature review presents a summary of the different test methods for measuring aggregate resistance to polishing, abrasion, and breakage.
- Chapter III discusses the analysis of variability in AIMS and Micro-Deval measurements. Measurements were conducted at the Texas Transportation Institute (TTI) and Texas Department of Transportation (TxDOT).
- Chapter IV describes new experimental methodologies to assess aggregate resistance to polishing, abrasion, and breakage. The methodologies rely on the AIMS and Micro-Deval measurements.
- Chapter V includes the conclusions and recommendations of this thesis.

CHAPTER II

LITERATURE REVIEW

INTRODUCTION

This literature review focuses on the significance of aggregate resistance to polishing characteristics and degradation (abrasion and breakage) on HMA pavement performance. A review of test methods that have been used for measuring these aggregate characteristics is also provided. The advantages and disadvantages of these methods are also discussed.

AGGREGATE POLISHING AND DEGRADATION CHARACTERISTICS

Aggregate properties influence different aspects of HMA performance. HMA performance parameters affected by aggregate properties are permanent deformation, fatigue cracking, frictional resistance, thermal cracking, and raveling (Kandhal and Parker 1998). Many aggregate properties are related to those performance parameters, such as gradation and size, aggregate particle shape and surface texture, porosity, cleanliness, toughness and abrasion resistance, durability and soundness, expansive characteristics, polish and frictional characteristics, and mineralogy and petrography (Kandhal and Parker 1998).

Research conducted under National Cooperative Highway Research Program NCHRP 4-30A has highlighted in detail the influence of aggregate shape characteristics

on HMA properties and performance (Masad et al. 2005). This study showed that shape, angularity, and texture are all important characteristics that should be quantified to better predict pavement performance. McGahan (2005) conducted comprehensive statistical analyses that related aggregate shape characteristics to several HMA mechanical properties. He concluded that aggregate shape characteristics are very important in influencing these mechanical properties. In fact, McGahan (2005) found that aggregate shape characteristics have a stronger relationships with mechanical properties than other mix properties such as binder grade and voids in mineral aggregates (VMA).

HMA pavement skid resistance depends on the microtexture and macrotexture of its surface. Dahir (1979) and Forster (1989) referred to 0.5 mm as a dividing line between macrotexture and microtexture. Microtexture is mainly dependent on aggregate shape characteristics; while, macrotexture is a function of mix properties, compaction method, and aggregate gradation (Kandhal and Parker 1998, Crouch et al 1995). Aggregate resistance to polishing affects asphalt pavement microtexture and skid resistance, which is considered a safety parameter. HMA surface frictional or skid resistance must maintain a minimum acceptable safe limit (Bloem 1971). One way that this safe limit can be achieved is through the use of aggregates with high resistance to polishing. Abdul-Malak et al. (1996) indicated that coarse aggregates at the surface are the main source of HMA pavement surface texture. He states that this is a result of the fact that the friction force is a result of the contacting points between vehicle tires and the HMA pavement surface, and coarse aggregates are responsible for developing these contacts points.

Henry and Dahir (1979) indicated that HMA macrotexture allows faster removal of water between the tire and the HMA pavement surface especially at high speeds; on the other hand, microtexture influences where water penetrates the surface and reduces skid resistance at both high and low speeds. Skid resistance of the HMA pavement surfaces is supposed to be adequate both right after construction and also after being opened to traffic, and so aggregates that resist polishing and wear are desired (Bloem 1971).

Hogervorst (1974) reported that the change of skid resistance with vehicle speed depends on both its microtexture and macrotexture (Fig. 2.1). Microtexture defines the level of skid resistance, but skid resistance decreases as vehicle speed increases. Macrotexture will control the magnitude of reduction of skid resistance as speed increases.

Fig. 1 : Relationship between the coefficient of friction measured in the wet condition and speeds for the road surfaces listed above.

Fig. 2.1. Skid resistance relationship with surface texture (After Hogervorst 1974)

Aggregate resistance to degradation (abrasion and breakage) is another important aggregate property that is related to several HMA performance parameters. Aggregates are exposed to degradation during production and construction before the pavement is in service. Degradation during construction affects the overall gradation; as such, the field produced mix will be different from the laboratory designed one (Wu et al. 1998).

New generations of asphalt mixes such as OGFC and SMA rely on stone-to-stone contacts in transferring applied stresses within the aggregate structure. This stress transfer mechanism imposes high contact stresses at the contact point that might lead to aggregate fracture and compromise the mix performance (Gatchalian

2005). Therefore, there is a need to develop test methods to assess aggregate resistance to fracture during compaction and under traffic loads. In a recent study, Gatchalian (2005) used conventional and imaging techniques to assess aggregate fracture in SMA mixes. He found that some aggregates do experience significant crushing in SMA, and he recommended using the Aggregate Imaging System (AIMS) to measure change in aggregate angularity after Micro-Deval testing and changes in gradation after compaction as measures of aggregate resistance to fracture.

AGGREGATE POLISHING TESTS

There are different methods available for measuring aggregate resistance to polishing and loss of frictional characteristics. Some of these methods have been used widely for a long time, while others have only been used in certain countries and laboratories, and some have recently been developed and are still in the evaluation process.

The British wheel/pendulum method, also known as polished-stone value (PSV), is one of the most widely used methods for measuring frictional properties of aggregates. Critical review of this method showed that test procedures differ among countries and even among state highway agencies in the United States. This test is also documented in ASTM E303 and ASTM D3319 test methods. ASTM provides two different specifications: one for the polishing procedure, and the other for the use of the British pendulum to measure friction. The Texas Department of Transportation (TxDOT) procedure for this test is Tex-438-A under the name “Accelerated Polish Test for Coarse Aggregates.” The general concept and steps are similar among the different procedures,

although they differ in some details such as type of polishing machine used and polishing time.

The British wheel/pendulum method procedure relies on preparing aggregate coupons that consist of aggregates glued to a plate. These coupons are polished using a polishing wheel for a certain period of time. Then, the British pendulum is used to measure the friction value of the aggregate coupons, which is called the polish value (PV). A higher PV indicates aggregates with higher frictional properties and better skid resistance.

Many studies have been conducted to evaluate the British wheel/pendulum test. Won and Fu (1996) evaluated the Tex-438-A test procedure and revealed many issues concerning this test. They found that the PV resulting from this test has very high variability. The study results attributed the high variability to the dependency of the PV on several factors that include;

- Coupon curvature: This factor may result in a change of up to 2 PV.
- Aggregate arrangement: Heterogeneous aggregates such as gravel contain some sandy particles that will provide more friction than other particles. Up to a 10 PV decrease was obtained when sandy particles were grouped rather than dispersed.
- Slider load: A 4 PV change was reported due to changes in slider load within ASTM limits.
- Number of swings: The slider itself polishes aggregates each time, and the polished value changes with number of swings.

- Aggregate sampling techniques: Obtaining aggregates through proper sample splitting is recommended rather than picking of aggregates.

Perry et al. (2001) studied the PSV test and concluded that it is not a good test to predict the skid resistance of aggregates. This conclusion was based on findings that the test result depends on aggregate size. Smith and Fager (1991) pointed out some issues regarding the use of the British pendulum as a measure of polishing. They reported that changing the pendulum pad changes the results, although the two pads used in the study met the specification. Kandhal et al. (1993) presented the categorization of PV for both limestone and gravel aggregates as shown in Figs. 2.2 and 2.3.

Fig. 2.2. Polish value percentages histogram for limestone (After Kandhal et al. 1993)

Fig.2.3. Polish value percentages histogram for gravel (After Kandhal et al. 1993)

As shown in Figs. 2.2 and 2.3, 59% of limestone aggregates are between the values 28 and 32, while 75% of gravel aggregates results are in this same small range. These results indicate that it is hard to distinguish between aggregates using this test.

Another test that has been used for measuring aggregate polishing is the Penn State Reciprocating Polishing Machine Method (Nitta et al. 1990). A schematic diagram of the polishing machine for this test is presented in Fig. 2.4. This machine is portable and is capable of polishing aggregates or pavement mixtures in the laboratory or in the field. The machine applies a rubber pad back and forth over a specimen surface to be polished, while water and abrasive are charged to the specimen surface.

FIG. 1—Schematic of Penn State Reciprocating Polisher.

| Slurry flow rate | 200 cc/min |

Fig. 2.4. Schematic of Penn State Reciprocating Polisher (After Nitta et al. 1990)

Mullen et al. (1971) suggested two different laboratory methods for evaluating aggregate polishing. The first test is called the Circular Track Wear method. This method is based on polishing pavement samples prepared from aggregates that need to be evaluated. Subsequently, pavement samples are placed in a circular track, which are then polished for 16 hours using small-diameter tires. The British pendulum is also used in this process to obtain the PV. Therefore, some of the limitations of the British pendulum are inherited in this test. The second test recommended by Mullen et al. (1971) is called the Jar Mill Wear method, which also uses the British pendulum to find

the PV for pavement samples. However, the polishing method is different. Aggregates are polished first and then used to prepare pavement samples, which are tested using the British pendulum. Aggregate polishing is conducted using jar mill with flint pebbles as abrasive charge in dry condition. Some aggregates required about 120 hours of polishing to reach the terminal polishing.

As a result of a long-term multi-phase project initiated by Tennessee Department of Transportation (TDOT), Crouch et al. (1995, 1996, 2001, and 2005) developed two methods for evaluating aggregate resistance to polishing in asphalt surfaces. The first method is called the Tennessee Terminal Textural Condition Method (T^3CM). This method is based on the idea of polishing an aggregate sample until it reaches its terminal texture condition. The terminal texture condition represents the state in which aggregate particles reach their minimum angularity and surface roughness. As part of the T^3CM , the Los Angeles abrasion and impact machine is used to achieve the terminal texture condition. However, no steel balls are used as in the case for the standard Los Angeles test, and the test continues until terminal texture condition is reached. The texture condition of the aggregate sample is assessed using the T^3CM uncompacted voids content apparatus (Fig. 2.5). This apparatus measures the percent of uncompacted voids in an aggregate sample. The percent of voids is used as an indication of aggregate angularity and texture.

Figure 1. Schematic T³CM Uncompacted Voids Content Apparatus Modified AASHTO T 304

Fig. 2.5. Schematic of T³CM Uncompacted Voids Content Apparatus (After Crouch et al. 2005)

The other method developed by Crouch et al. (2005) was the Micro-Deval Voids at 9-hours (MDV9). This method was developed as a replacement of the T³CM test. The changes were conducted to achieve:

- Smaller sample size (60 kg for T³CM)

- Reduced laboratory time (30 to 47 hours for T³CM)
- Specified stopping point (no specified stopping time for T³CM)

In the MDV9 test, the Micro-Deval machine is used to polish aggregates. An aggregate sample of 4500 gm is polished for 9 hours.

AGGREGATE ABRASION TESTS

The L.A. Abrasion and Impact Test (AASHTO T 96) is the most widely used method for measuring aggregate resistance for abrasion and aggregate toughness (Kandhal and Parker 1998). In this test aggregates are mixed with steel balls of specific size and weight in a steel drum. Drum rotation promotes interaction between aggregates and steel, which introduces different mechanisms of abrasion, impact, and grinding. The lifting and dropping action of aggregates introduces very high impact forces, which makes the test a measure of impact resistance rather than abrasion resistance. Originally, the test name was the L.A. Abrasion Test, but the addition of ‘impact’ to its name was to recognize that this test measures aggregate resistance to impact rather than abrasion (Rogers 1998). According to the AASHTO T 96, this test is a measure of aggregate degradation due to abrasion, impact, and grinding. However, Rogers (1998) indicated that studies revealed that this test measures mostly aggregate resistance to mechanical breakdown. Table 2.1 presents the specific details of the test according to the AASHTO T 96 procedure.

Table 2.1. AASHTO T 96 Los Angeles Test Specifications Summary

| | |
|--------------------------------|---|
| Aggregate Material Size | Many gradings (max. size up to 3 in) |
| Rotation Speed | 30 to 33 rpm |
| Total Revolutions | 500 (1000 for large aggregate size grading) |
| Steel Ball Size | 46.8 mm diameter |
| Abrasion Charge | 2500 to 5000 g -6 to 12 steel balls- (varies with aggregate size) |
| Determining the Loss | Percent passing sieve No. 12 |

The second test that has been used for measuring abrasion resistance is the Micro-Deval test (AASHTO TP 58-00). This test was originally developed in the 1960s in France. The test measures the durability and abrasion resistance of aggregates through abrasion between aggregate particles and between aggregate particles and steel balls in the presence of water (Cooley and James 2003). The Micro-Deval test is standardized in AASHTO TP 58-00 “Standard Test Method for Resistance of Coarse Aggregate to Degradation by Abrasion in the Micro-Deval Apparatus,” and in Tex-461-A procedure, “Degradation of Coarse Aggregate by Micro-Deval Abrasion.” Table 2.2 presents the specific details of the test according to the AASHTO TP 58-00 procedure. Fig. 2.6 shows schematic cross section of interaction between aggregates and steel balls in presence of water in the Micro-Deval.

Table 2.2. AASHTO TP 58-00 Micro-Deval Test Specifications Summary

| | |
|--------------------------------|-----------------------------------|
| Aggregate Material Size | 4.75 to 16.0 mm (3 grading types) |
| Rotation Speed | 100 \pm 5 rpm |
| Total Revolutions | 9500 to 12000 |
| Steel Ball Size | 9.5 mm diameter |
| Abrasion Charge | 5000 \pm 5 g |
| Determining the Loss | Percent passing sieve No. 16 |

**Fig. 2.6.** Schematic of interaction between aggregates and steel balls in presence of water in the Micro-Deval

Several studies have conducted comparisons between the Micro-Deval and L.A. Abrasion and Impact Tests. A few points summarizing these studies are given herein:

- The L. A. Test is believed to measure the impact resistance of aggregates rather than abrasion resistance (Lane et al. 2000).
- The wet conditions in the Micro-Deval test give it the ability to simulate the field condition of aggregates better than the dry state in the L.A. Test (Rogers 1998).
- The interaction between aggregates and steel balls in the Micro-Deval jar induces more tumble action than impact (Meininger 2004).
- Los Angeles test results have poor correlation with field performance (Senior and Rogers 1991).
- Micro-Deval results had mixed correlations with aggregate performance histories (Cooley and James 2003). This mixed correlation could be attributed to the difficulty of ranking aggregates performance simply based on experience with these aggregates.

Other tests for measuring aggregate resistance to abrasion are the “Aggregate Abrasion Test,” and the “Nordic Ball Mill Test.” These two tests are more widely used in Europe than in the United States. The Aggregate Abrasion Test is a dry test and it uses a flat rotating steel plate to abrade aggregates, while the Nordic Ball Mill Test has minor differences from the Micro-Deval Test. Table 2.3 provides a comparison between the two tests (Hunt 2001).

Table 2.3. Comparison of Micro-Deval and Nordic Ball Mill Tests Specifications

| | Micro-Deval | Nordic Ball Mill |
|---|------------------------------------|----------------------------------|
| Aggregate Material Size | 4.75 to 16.0 mm (3 grading types) | 11.2 to 16.0 mm |
| Rotation Speed | 100 \pm 5 rpm | 90 \pm 3 rpm |
| Total Revolutions | 9,500 to 12,000 | 5400 |
| Steel Ball Size | 9.5 mm diameter | 15.00 mm diameter |
| Abrasion Charge | 5000 \pm 5 g | 7000 \pm 10 g |
| Determining the loss | Percent passing sieve No. 16 | Percent passing 2 mm sieve |

AGGREGATE IMAGING SYSTEM (AIMS)

AIMS determines shape characteristics of aggregate through image processing and analysis techniques. AIMS equipment consists of a computer automated unit which includes aggregate measurement tray with marked grid points at specified distances along x and y axes. Coarse aggregate sample is placed on the specified grid points, while fine aggregate sample is spread uniformly on the entire tray. The system also equipped with top lighting, back lighting and a camera unit. Shape characteristics of aggregate; shape, angularity, and surface texture are produced by AIMS software which analyzes the aggregate images. Aggregate texture is quantified using wavelet analysis method (texture index); aggregate angularity is described by measuring the irregularity of a particle surface using the gradient and radius methods (Angularity index); shape is

described by 2D form and 3D form (Sphericity). All details of AIMS and the analysis principals are given by Al-Rousan (2004).

SUMMARY

The literature review findings indicate that current methods for measuring aggregate resistance to polishing have several drawbacks. Among these drawbacks are the long time it takes for preparing and polishing aggregate specimens, and the influence of other factors besides texture on the results. For example, the British wheel/pendulum method results depend on the coupon curvature and size of aggregates.

Several studies reported that the Micro-Deval test is a good method for assessing aggregate resistance to abrasion. However, the weight loss measured in this test could be attributed to either abrasion or breakage. Therefore, the Micro-Deval alone cannot separate the influence of abrasion from breakage.

CHAPTER III

ANALYSIS OF VARIABILITY IN AIMS AND MICRO-DEVAL MEASUREMENTS

OVERVIEW

This chapter includes the analysis of variability of the Aggregate Imaging System (AIMS) and the Micro-Deval. AIMS repeatability and reproducibility have been evaluated in previous studies through the analysis of multiple measurements conducted by the same operator, and measurements conducted by three operators. However, these measurements were conducted using the same AIMS unit.

This chapter documents the results of analyzing variability in measurements conducted using two AIMS units located at the TTI and TxDOT laboratories. In addition, variability in Micro-Deval measurements conducted in two different laboratories are analyzed in this chapter. The variability analysis is necessary since the methods recommended in Chapter IV rely on the results from the AIMS and Micro-Deval tests. The reliability of these methods obviously depends on the level of variability in the test methods used.

INTRODUCTION

Bathina (2005) conducted a statistical analysis of AIMS measurements in order to determine their repeatability, reproducibility, and sensitivity. The results of this study indicated that AIMS is highly repeatable. The maximum coefficient of variation (C.V)

was 13.9 percent in measuring the texture of random samples from the same aggregate and 4.9 percent in measuring the same aggregate sample, while the C.V of reproducibility (variation among three operators) was 16.3 percent in measuring random samples. All measurements by Bathina (2005) were conducted using a single AIMS unit. AIMS was also found to be sensitive to changes in aggregate properties. In the same study, AIMS results were compared with other test methods in terms of repeatability and reproducibility, and the conclusion was that AIMS has excellent repeatability and reproducibility compared to other test methods.

Bathina (2005) implemented a statistical method to compare AIMS results for two aggregates using aggregate shape classification categories developed by Al-Rousan (2004). Categories for texture and gradient angularity are shown in Table 3.1. Details on the mathematical derivation of the image analysis methods are given by Al-Rousan (2004)

Table 3.1. Gradient Angularity and Texture Categories

| Aggregate Property | Sub Class | | | | |
|----------------------------|------------------|-------------|---------------|------------------|----------------|
| | 1 | 2 | 3 | 4 | 5 |
| Gradient Angularity | Rounded | Sub Rounded | Sub Angular | Angular | |
| Texture | Polished | Smooth | Low Roughness | Medium Roughness | High Roughness |

VARIABILITY BETWEEN TWO AIMS UNITS

Angularity and Texture of Aggregates

Materials and Experiment

The original plan was to analyze variability in measurements conducted at the TTI and TxDOT laboratories on a wide range of aggregates, where one operator would do all measurements at TTI and another operator would conduct all measurements at TxDOT. However, during the data collection phase, it was found that the AIMS measurements at TxDOT were performed by several operators, and it was not possible to identify samples that were measured by each of the operators. This situation prompted conducting another experiment in which the same aggregates are scanned using the two AIMS units by the same operator. Aggregates that were used in this evaluation are listed in Table 3.2.

Table 3.2. List of Aggregates used Assessing AIMS Variability

| Aggregate # | TxDOT Label | Aggregate Type | After Micro-Deval (A) or Before Micro-Deval (B) |
|--------------------|--------------------|-----------------------|--|
| 1 | 05-0213 | Crushed Limestone | A |
| 2 | 05-0231 | Crushed Gravel | A |
| 3 | 05-0519 | Crushed Limestone | A |
| 4 | 05-0532 | Crushed Limestone | A |
| 5 | 05-0543 | Partly Crushed Gravel | B |
| 6 | 05-0545 | Crushed Limestone | B |
| 7 | 05-0643 | Crushed Limestone | B |
| 8 | 05-0649 | Crushed Limestone | B |
| 9 | 05-0693 | Crushed Gravel | B |
| 10 | 05-0708 | Crushed Sandstone | B |

As shown in this table, some of the aggregates used in this analysis were subjected to the Micro-Deval abrasion. These aggregates were included in order to ensure that a wide range of aggregate characteristics are accounted for in the analysis.

The same exact aggregate particles were scanned using the two AIMS units at TTI and TxDOT by the same operator. As listed in Table 3.3, three different sizes of each of the aggregates in Table 3.2 were scanned and analyzed for angularity and texture. That is, a total of 60 scans were conducted at each location (30 scans for angularity and 30 scans for texture).

Table 3.3. Aggregate Sizes Scanned in This Research

| Passing | Retained |
|----------------|-----------------|
| 1/2 in | 3/8 in |
| 3/8 in | 1/4 in |
| 1/4 in | # 4 |

In addition, all measurements from all sizes were combined and analyzed. Aggregate size will be referred to in this study by the retaining sieve (3/8", 1/4", and # 4).

Statistical Methods and Results

Three statistical analysis methods were used to compare the results from the two AIMS units by using SPSS software version 11.5. The first analysis is to calculate the average characteristics for each aggregate type, plotting the averages of the two AIMS units, and

calculating the fitted line equation with its R^2 . Such plots will give a general idea of how good the results are. Figs. 3.1, 3.2, 3.3, and 3.4 represent the texture analysis results, while Table 3.4 shows the fitting equations. It can be seen that the R^2 values in Table 3.4 indicate an excellent correlation between the TTI and TxDOT measurements. Also, the equations in Table 3.4 show that the measurements are close to the equality line with small biases.

The gradient angularity results are shown in Figs. 3.5, 3.6, 3.7, and 3.8. Very good correlation exists between the angularity measurements, but the correlation is not as good as the texture results. This is clear in the R^2 and fitting equations shown in Table 3.5. It is important to mention that the higher intercept numbers for angularity compared with texture are expected as the magnitude of gradient angularity is in the thousands, while the magnitude for texture is in the hundreds.

Fig. 3.2. AIMS Analysis of Variability: #4 Size Texture Results

Fig. 3.3. AIMS Analysis of Variability: 1/4" Size Texture Results

Fig. 3.4. AIMS Analysis of Variability: 3/8" Size Texture Results

Table 3.4. Linear Model Results for Texture Analysis

| | R^2 | Linear Equation |
|-------------------------|--------|--------------------------------------|
| Combined 3 sizes | 0.948 | $TTI = 0.8819 \times TxDOT + 9.3853$ |
| 1/4" size | 0.9255 | $TTI = 0.8899 \times TxDOT + 6.5496$ |
| 3/8" size | 0.9232 | $TTI = 1.0222 \times TxDOT - 4.1923$ |
| #4 size | 0.9321 | $TTI = 0.7688 \times TxDOT + 19.538$ |

**Fig. 3.5.** AIMS Analysis of Variability: Combined Sizes Gradient Angularity Results

Fig. 3.6. AIMS Analysis of Variability: #4 Size Gradient Angularity Results

Fig. 3.7. AIMS Analysis of Variability: 1/4" Size Gradient Angularity Results

Fig. 3.8. AIMS Analysis of Variability: 3/8" Size Gradient Angularity Results

Table 3.5. Linear Model Results For Gradient Angularity Analysis

| | R^2 | Linear Equation |
|-------------------------|--------|--------------------------------------|
| Combined 3 sizes | 0.9339 | $TTI = 0.9688 \times TxDOT - 117.06$ |
| 1/4" size | 0.8662 | $TTI = 0.9377 \times TxDOT + 13.409$ |
| 3/8" size | 0.7552 | $TTI = 0.8474 \times TxDOT + 65.829$ |
| #4 size | 0.9746 | $TTI = 0.9887 \times TxDOT - 99.156$ |

The second statistical analysis method involved calculating the confidence interval (C.I) for the difference between the means using the following equation:

$$(\bar{X}_{TTI\ i,j} - \bar{X}_{TxDOT\ i,j}) \pm 1.96 \times \sqrt{(\sigma_{TTI\ i,j}^2 + \sigma_{TxDOT\ i,j}^2)} \quad (1)$$

Where

$\bar{X}_{TTI\ i,j}$ = estimated value of the mean for aggregate property scanned at TTI

$\bar{X}_{TxDOT\ i,j}$ = estimated value of the mean for aggregate property scanned at TxDOT

$\sigma_{TTI\ i,j}$ = standard error in estimation of the mean for aggregate property at TTI

$\sigma_{TxDOT\ i,j}$ = standard error in estimation of the mean for aggregate property at TxDOT

i = aggregate number with values of 1, 2, ..., 10

j = aggregate size with values of 1, 2, 3, 4, where 4 indicates the combined sizes.

The interval in Eq. (1) is at 95 percent confidence. If the C.I contains zero, then the difference between the mean values of the aggregate property between TTI and TxDOT can be considered zero and so the two measurements have the same mean value.

The estimated means and standard errors are all given in Appendix A, and the C.Is for the difference in means between the TTI and TxDOT results are in Appendix B. Table 3.6 summarizes the C.I's results for texture. It is obvious that in most cases the C.I contain zero indicating that the TTI and TxDOT texture measurements have the same mean value.

A summary of the C.Is for angularity is shown in Table 3.7. Most of the C.Is contain zero. For the combined three sizes, the reason for three intervals not containing

zero is attributed to the 3/8" size results. The correlation for the 3/8" size was not as good as the other results. Nevertheless, the results are still acceptable from practical point of view.

Table 3.6. Texture C.Is Results Summary

| | # of C.I containing zero |
|-------------------------|---------------------------------|
| Combined 3 sizes | 9 |
| 1/4" size | 8 |
| 3/8" size | 9 |
| #4 size | 10 |

Table 3.7. Gradient Angularity C.Is Results Summary

| | # of C.I containing zero |
|-------------------------|---------------------------------|
| Combined 3 sizes | 7 |
| 1/4" size | 10 |
| 3/8" size | 6 |
| #4 size | 10 |

The third statistical analysis was in accordance with the categorical analysis employed by Bathina (2005). The chi-square goodness of fit test is used in this chapter to analyze differences in measurements conducted in each of the aggregates listed in Table 3.2. The following hypotheses were used in the analysis:

- Null hypothesis: the two aggregates are not different in at least one subclass.
- Alternative hypothesis: the two aggregates are different in at least one subclass.

The p-value of the Pearson chi-square provides the test for the null hypothesis using 95 percent confidence. If the p-value is less than 0.05, then the null hypothesis is rejected; on the other hand, if the p-value is higher than 0.05, the null hypothesis cannot be rejected. Further knowledge of the difference in each subclass can be obtained by observing the standard residual. If the standard residual for a subclass is greater than 1.96 then the difference in that subclass is believed to be a contributing factor.

An example of the texture and angularity results for aggregate 5 are shown in Tables 3.8 and 3.9, respectively. In aggregate 5, all the chi-square p-values are higher than 0.05 and all the standard residual are less than 1.96. Therefore, all the subclasses are not different from each other. The same table is generated for each of the aggregates and all are given in Appendix D. Examples of full chi-square tables are in Appendix E.

Tables 3.10 and 3.11 provide a summary of the categorical analysis results for the 10 aggregates. It is evident that the majority of measurements indicated that the p-values are higher than 0.05, and the standard residuals are less than 1.96. Again, this analysis supports the main finding that the texture and angularity measurements in both the TTI and TxDOT AIMS units are similar.

Table 3.8. Chi-Square Summary Table for Texture Results of Aggregate 5

| Aggregate 5 | Size Compared | Standard Residual | | | | | Chi-Square p-value |
|----------------|------------------|-------------------|------|------|------|------|-----------------------|
| | | Subclass | | | | | |
| Texture | | 1 | 2 | 3 | 4 | 5 | |
| TxDOT | Combined | 0.4 | -0.6 | 0.5 | -0.4 | -0.7 | 0.580 |
| TTI | | -0.4 | 0.6 | -0.5 | 0.4 | 0.7 | |
| TxDOT | 3/8" | 0.4 | -0.4 | 0.3 | -1.4 | | 0.184 |
| TTI | | -0.4 | 0.4 | -0.3 | 1.4 | | |
| TxDOT | 1/4" | 0.2 | -0.6 | 0.6 | 0.3 | -1.0 | 0.429 |
| TTI | | -0.2 | 0.6 | -0.6 | -0.3 | 1.0 | |
| TxDOT | #4 | 0.3 | -0.9 | 0.6 | | | 0.297 |
| TTI | | -0.3 | 0.9 | -0.6 | | | |

Table 3.9. Chi-Square Summary Table for Gradient Angularity Results of Aggregate 5

| Aggregate 5 | Size Compared | Standard Residual | | | | Chi-Square p-value |
|---------------------|---------------|-------------------|------|------|------|--------------------|
| | | Subclass | | | | |
| Gradient Angularity | | 1 | 2 | 3 | 4 | |
| TxDOT | Combined | -0.1 | 0.4 | -0.4 | -1.0 | 0.450 |
| TTI | | 0.1 | -0.4 | 0.4 | 1.0 | |
| TxDOT | 3/8" | -0.1 | 0.2 | 0.4 | -1.0 | 0.504 |
| TTI | | 0.1 | -0.2 | -0.4 | 1.0 | |
| TxDOT | 1/4" | 0.5 | 0.2 | -1.5 | -1.0 | 0.073 |
| TTI | | -0.5 | -0.2 | 1.5 | 1.0 | |
| TxDOT | #4 | -0.3 | 0.6 | -0.4 | | 0.547 |
| TTI | | 0.3 | -0.6 | 0.4 | | |

Table 3.10. Categorical Analysis Results Summary for the 10 Aggregate's Texture

| | # of p<0.05 Cases | # of Cases with Particular Subclass is Different |
|-------------------------|-------------------|--|
| Combined 3 sizes | 0 | 0 |
| 1/4" size | 1 | 0 |
| 3/8" size | 0 | 0 |
| #4 size | 0 | 0 |

Table 3.11. Categorical Analysis Results Summary for the 10 Aggregate's Angularity

| | # of p<0.05 Cases | # of Cases with Particular Subclass is Different |
|-------------------------|-------------------|--|
| Combined 3 sizes | 1 | 1 |
| 1/4" size | 3 | 1 |
| 3/8" size | 3 | 1 |
| #4 size | 1 | 0 |

For each aggregate, a plot of columns that represent how much percent of aggregate belongs to each subclass of aggregate texture is useful to compare the results between TTI and TxDOT. Figs 3.9 and 3.10 present the plots of angularity and texture for aggregate 5. The same plot was generated for all the 10 aggregates and all these plots are in Appendix C. In general, the results support the statistical results that the majority of TTI and TxDOT measurements are similar.

Fig. 3.10. Aggregate 5 Gradient Angularity Subclasses

Texture of Polishing Coupons

Materials and Experiment

Aggregate coupons were polished using the British polishing wheel. Then, they were scanned using the two AIMS to analyze texture. The coupon texture measurements consist of placing four coupons on the lighting table, then performing texture analysis at magnification 12 with a moving interval of 12 mm in the x-direction and 8 mm in the y-direction. The microscope is auto-focused prior to capturing each image, as the coupon curvature affects the focus point at each point.

Fifty coupons of various aggregates were used in this analysis. Table 3.12 summarizes the aggregate types used in these coupons.

Table 3.12. Aggregate Types Used in Coupons

| Aggregate Type | Number of Coupons |
|-----------------------|-------------------|
| Limestone | 29 |
| Gravel | 14 |
| Lightweight Aggregate | 1 |
| Igneous Rock | 1 |
| Sandstone | 3 |
| Miscellaneous | 2 |

Statistical Analysis and Results

The average texture results are compared as shown in Fig. 3.11. It is obvious that there is excellent correlation between the coupon measurements using the two AIMS units.

The R^2 is equal to 0.9114, and the equation of linear fit is $TTI = 1.1357 \times TxDOT - 15.248$.

the deviation from the equality line is accepted from practical point of view

The confidence interval for the difference between the means was calculated using Eq. (1). Tabulated results of estimated means and standard errors are given in Appendix A, and the confidence intervals for the difference in means between TTI and TxDOT results are shown in Appendix B. Based on these results, it can be seen that only 8 C.Is out of 50 do not contain zero. The C.I containing zero indicates that the TTI and TxDOT texture measurements have the same mean value. It must be kept in mind, too, that for the statistical analysis with the use of 95 percent as confidence level, there is always a chance for 5 percent of the data analyzed to be rejected (C.I do not contain zero) while in reality it shouldn't be rejected (C.I contain zero).

The categorical analysis indicated that only six cases have the p-value less than 0.05. Plots and tables for categorical analysis results are given in Appendices C and D, respectively.

Fig. 3.11. Aggregate Polished Coupons Texture Results

MICRO-DEVAL VARIABILITY

Materials and Experiments

Aggregates were tested in the Micro-Deval at both the TTI and TxDOT laboratories.

The Micro-Deval test is destructive. Aggregates are subjected to abrasion, polishing, and breakage. Consequently, the same exact sample can not be tested in both machines.

Available for comparison are fifty nine aggregate sample results, and the comparison is based on the Micro-Deval weight loss. Aggregate type and weight loss results are listed in Table 3.13.

Statistical Analysis and Results

The results plotted in Fig. 3.12 show that the two tests produce almost the same results, except for a few cases. The statistical analysis involves fitting a linear model to the data, and then determining the confidence intervals for the slope and the intercept of this model using the SPSS software version 11.5. The liner regression model is summarized in Table 3.14.

Table 3.13. Micro-Deval Analysis of Variability: Aggregate Types and Weight Loss Results

| TxDOT Label | Aggregate Type | TTI | TxDOT |

| 05-0708 | Sandstone | 8.0 | 8.1 |

Fig.3.12. Micro-Deval Analysis of Variability: Weight Loss Results (All Data Points)

Table 3.14. Micro-Deval Analysis of Variability: Weight Loss Linear Model Results (All Data Points)

| | | Confidence Interval | |
|----------------------|-------|---------------------|-------------|
| | | Lower Limit | Upper Limit |
| Slope | 0.842 | 0.77 | 0.915 |
| Intercept | 1.111 | -0.21 | 2.432 |
| R² | 0.905 | | |

It can be noticed from Fig. 3.12 that there are two points that do not follow the general trend. These two points were investigated and it was found that the TTI measurements of these two aggregates were not accurate as the number of revolutions at the end of the

Micro-Deval test were below the lower acceptable limit. According to the Micro-Deval test specification those two results must be discarded. Therefore, the statistical analysis was repeated after removing the two points with results as shown in Fig. 3.13. The new liner regression model is summarized in Table 3.15. The R^2 increased from 0.905 to 0.972, while the intercept decreased from 1.111 to 0.313. This intercept became closer to zero, which is the intercept of the equality line. Although the confidence intervals for the intercept contained zero for the two cases, it is closer to equally spread around zero in the second case. The slope value increased from 0.842 to 0.918, indicating that it became closer to the equality line. Both confidence intervals for the slope in the two cases did not contain 1, but it is closer to 1 in the second case.

Fig. 3.13. Micro-Deval Analysis of Variability: Weight Loss Results (Excluding Outliers)

Table 3.15.Micro-Deval Analysis of Variability: Weight Loss Linear Model Results
(Excluding Outliers)

| | | Confidence Interval | |
|----------------------|-------|---------------------|-------------|
| | | Lower Limit | Upper Limit |
| Slope | 0.918 | 0.876 | 0.960 |
| Intercept | 0.313 | -0.425 | 1.050 |
| R² | 0.972 | | |

The SPSS output results are presented in Appendix F. Residual analysis is important as it provides the proof for the goodness of fit using the linear model. Residual analysis for the two fitted models showed that the second one is much better, as the residual is more spread out and closer to the normal distribution than in the first one.

SUMMARY

In this chapter, the results from two AIMS measurements were compared. The first comparison was for angularity and texture of aggregate samples. All statistical analysis methods supported the main finding that measurements from the two AIMS units were not statistically different.

The texture measurements on polishing coupons were also compared. The same exact coupons were scanned using the two units. More than 80 percent of samples were not statistically different when measured using the two units.

The difference in Micro-Deval measurements conducted using two machines was also analyzed in this chapter. Excellent correlation was found between the measurements of the two machines. Also, the results from the two machines are not different statistically.

CHAPTER IV

DEVELOPMENT OF A METHODOLOGY FOR MEASURING AGGREGATE RESISTANCE TO POLISHING, ABRASION, AND BREAKAGE

OVERVIEW

This chapter includes the development of new methodologies for measuring aggregate resistance to polishing and degradation (abrasion and breakage). Polishing is the loss of aggregate surface texture, and abrasion is the reduction in aggregate size due to the loss of the surface angularity and texture, while breakage is the fracture of aggregate particle. The developed methodologies utilize the AIMS and Micro-Deval measurements.

Aggregates are expected to encounter degradation during production, transportation, construction, and compaction. In addition, some new generation mixes such as Stone Matrix Asphalt (SMA) and Open Graded Friction Course (OGFC) rely on stone-to-stone contacts in transferring applied stresses through the aggregate structure. This stress transfer mechanism applies high contact stresses that can cause aggregate fracture. Therefore, it is desirable to use in these mixes coarse aggregates that are able to sustain these contact stresses without fracture.

Aggregate resistance to polishing is mainly related to HMA pavement surface skid resistance. As pointed out in the literature review, there are several drawbacks of current methods for measuring aggregate degradation. Among these drawbacks are the long time it takes for preparing and polishing specimens, and the influence of other

factors besides texture on the results. The Micro-Deval test results cannot distinguish between aggregate abrasion and breakage.

INTRODUCTION

Asphalt pavement frictional resistance, which is also known as skid resistance, is one of most important performance parameters due to its effect on travel safety. Frictional resistance of HMA must maintain a minimum acceptable safe limit. Skid resistance is a function of both the microtexture and macrotexture of the surface (Dahir 1979). The microtexture is mainly dependent on the aggregate shape characteristics; on the other hand, macrotexture is a function of mix design, compaction method, and aggregate gradation. According to Abdul-Malak et al. (1996), coarse aggregates at the surface are the main source of HMA pavement surface texture.

There are many methods available for measuring aggregate polishing resistance. The most widely used is the British wheel/pendulum method (ASTM E303 and ASTM D3319). However, many studies showed that the PV measured using the British pendulum is a function of many other factors besides aggregate texture (Won and Fu, 1996). These factors include the coupon curvature and aggregate size. In addition, most of the PV results of this test for a wide range of aggregates vary within a small range of 4 PV (Kandhal et al. 1993), which makes it difficult to distinguish among aggregate polishing resistance.

Crouch and Dunn (2005) developed two methodologies for measuring aggregate polishing. The first one is the Tennessee Terminal Textural Condition Method (T³CM)

in which the uncompacted voids content is measured in aggregates before and after abrasion in the Los Angeles machine. The second test is the Micro-Deval Voids at 9-hours (MDV9). In this test, uncompacted voids content is measured in an aggregate sample before and after 9 hours of abrasion in the Micro-Deval test.

Another important characteristic of aggregate that affects HMA properties is the resistance to degradation (abrasion and breakage). Aggregates are exposed to degradation during plant operations and under compaction. Degradation affects the overall gradation and so the field produced mix will be different from the laboratory designed one (Wu et al. 1998), Therefore, it is important to control aggregate degradation during construction.

Asphalt mixes such as OGFC and SMA rely on stone-to-stone contacts in transferring applied stresses within the aggregate structure. High contact stresses are present at the contact points which lead to aggregate fracture and reduction in load carrying capacity (Gatchalian 2005). Therefore, there is a need to develop a test method to assess aggregate resistance to fracture during compaction and under traffic loads. Gatchalian (2005) recommended the use of the Aggregate Imaging System (AIMS) to measure change in aggregate angularity after Micro-Deval testing, and changes in gradation after compaction as measures of aggregate resistance to fracture.

A METHODOLOGY FOR MEASURING AGGREGATE RESISTANCE TO POLISHING

Aggregate polishing is defined as the aggregate loss of its surface texture. The development of a methodology to measure the aggregate resistance to polishing can be achieved by three steps: (1) measure the initial aggregate texture, (2) polish the aggregates, and (3) measure their texture after polishing. The simplicity of the methodology will depend on the techniques used to perform these steps, and the time to carry out these steps.

In the developed methodology, AIMS is used to measure the aggregate texture. The operator needs only to do some simple steps to calibrate the system, and then the AIMS unit will operate through computer control to obtain images and analyze texture. AIMS takes around 15 to 20 minutes to scan a set of aggregates for texture and angularity, which is considered a short time. The Micro-Deval test is introduced as the polishing mechanism in this study. The Micro-Deval test is conducted according to the Tex-461-A procedure.

Preliminary Evaluation of the Proposed Methodology

Prior to the development of the new methodology, it was necessary to examine the ability of the Micro-Deval to polish aggregates, and the relationship between polishing of coupons using the Accelerated Polish Test (Tex-438-A) and aggregate polishing using the Micro-Deval.

Aggregate coupons and Micro-Deval aggregate samples were all prepared at the TxDOT laboratory. The TxDOT laboratory conducted the AIMS texture measurements on the coupons before and after polishing, and on aggregate samples before after the Micro-Deval. The TxDOT laboratory measured the PV using the British pendulum on the coupons.

The coupons were sent to the TTI laboratory after polishing where they were measured again using AIMS. Aggregate samples were also shipped to the TTI laboratory where they were measured using the Micro-Deval test and AIMS. Aggregates used in the two experiments were all from the state of Texas. Most of the aggregates are limestone and gravel, with some other types like sandstone, igneous rock, and lightweight aggregate.

Fig. 4.1 shows a plot of the aggregate texture index before Micro-Deval (BMD) against aggregate texture index after Micro-Deval (AMD). Most of the aggregates are to the right of the equality line, which is a proof that most of the aggregates had a higher texture index BMD, and that AIMS is capable of detecting changes in texture due to polishing by the Micro-Deval. Fig. 4.2 shows examples of images on one of the aggregates before and after Micro-Deval polishing. The loss of texture can even be seen visually in these images.

Fig. 4.1. Comparing Aggregate Texture Before and After Micro-Deval

Fig. 4.2. Aggregate Images: a) Aggregate Particles Before Micro-Deval, b) Aggregate Particles After Micro-Deval, c) Aggregate Surface Texture Before Micro-Deval, d) Aggregate Surface Texture After Micro-Deval

Fig. 4.3 shows the texture index of aggregates BMD versus the texture of coupons before polishing (BP); while the after polishing (AP) results are shown in Fig. 4.4. There is very good correlation (R^2) between texture of aggregates and texture

of coupons in both the before polishing and after polishing cases. This result supports that the Micro-Deval is able to polish aggregates, and this polishing effect is captured well by AIMS. Fig. 4.5 shows an example of a coupon before polishing and after polishing. As was the case for the aggregates in the Micro-Deval, the effect of polishing can be seen visually in these images.

Fig. 4.3. Relationship between Coupons and Aggregate Particles Texture

Fig.4.5. Example of a Coupon Before and After Polishing

Comparison of Aggregate Polishing Using the Proposed Methodology

An experiment was conducted to examine the effect of polishing time in the Micro-Deval on the texture index, and to determine the time needed for the texture to reach its terminal value. The six different aggregates listed in Table 4.1 were subjected to Micro-Deval polishing for different lengths of time of 15, 30, 45, 60, 75, 90, 105, and 180 minutes.

Table 4.1. Aggregate Types Used in Polishing Experiment

| Aggregate Number | Description |
|------------------|------------------------|
| 1 | Crushed Gravel |
| 2 | Hard Crushed Limestone |
| 3 | Soft Crushed Limestone |
| 4 | Traprock |
| 5 | Quartzite |
| 6 | Crushed Granite |

Two different procedures were followed in order to determine whether it is necessary to use different aggregate samples for the different polishing time durations, or if the same sample can be used for all time durations. In the first procedure, an aggregate sample was scanned using AIMS, and then it was tested in the Micro-Deval for 15 minutes. The sample was removed from the Micro-Deval and scanned in AIMS again. The same aggregate sample was returned to the Micro-Deval and tested for 15 more minutes, after which it was scanned using AIMS. This process was repeated until the cumulative time summed to 105 minutes then the sample is returned to the Micro-Deval for another 75 minutes.

In the second procedure, eight different samples from each aggregate were used. Each aggregate sample was tested for a certain time duration and was discarded after this

time duration. An example of the comparison between these two procedures is shown in Fig. 4.6. As can be seen, very similar results were obtained using the two procedures. It is recommended to use the second method in spite of the fact that it requires more material. The second procedure with different samples requires less time. Also, this procedure ensures that the Micro-Deval test is conducted at the same conditions for each of the time intervals irrespective of aggregate type. If the same aggregate sample is used for the different time durations, the washing of the fines after each interval affects the interaction between steel balls and aggregates.

Fig. 4.6. Comparing Results for Two Different Procedures of Proposed Methodology

Figure 4.7 shows the change of texture as a function of polishing time in the Micro-Deval for all six aggregates. Aggregate 1 is crushed gravel with low texture. The texture of this aggregate did not follow a certain trend with polishing time. The slight changes in texture can be attributed to the small differences among aggregate samples. Visual inspection of aggregates after the different time intervals showed that the aggregate texture changed very little, as the results in Fig. 4.7 indicate. This aggregate lost only 2.68 percent of its weight after 105 minutes, but 1 percent of its weight was lost after 15 minutes and 1.47 percent of its weight after 30 minutes.

Fig.4.7. Aggregate Texture as Function of Micro-Deval Time

Aggregate 2 is a crushed hard limestone. Aggregate texture started at 100 and changed slightly after 15 minutes of polishing. However, texture dropped rapidly afterward until it reached a texture value around 100. Aggregate 3 is a crushed soft limestone. The trend for this aggregate is similar to the trend for aggregate 2 as the texture value almost stabilize around value of 40. The Micro-Deval weight loss of this aggregate was 20.4 percent after 105 minutes in the Micro-Deval, which is the highest among all the six aggregates.

Aggregate 4 is a crushed traprock aggregate. The initial texture was 311, and it experienced rapid loss of texture until about 45 minutes, but the rate of losing texture decreased after that. Finally, texture almost stabilized in the last 30 minutes around a value 150.

Aggregate 5 is a quartzite aggregate, and did not lose much of its texture in the first 45 minutes. Aggregate 5 started losing texture for the following 45 minutes to reach a value around 120 and kept on losing texture with time. Aggregate 6 is a crushed granite. This aggregate did not lose much of its texture, and its texture reached a value of 184. Fig. 4.8 represents the texture distribution for aggregate 4 before and after the Micro-Deval. Fig. 4.9 represents the texture distribution for aggregate 6 before and after the Micro-Deval. It can be seen from the figures how the Micro-Deval polishing changed the texture distribution, and that aggregate 4 was more affected by the Micro-Deval than aggregate 6.

Fig. 4.8. Texture Distribution of Aggregate 4 Before and After Micro-Deval

Fig. 4.9. Texture Distribution of Aggregate 6 Before and After Micro-Deval

The results in Fig. 4.7 indicate that the Micro-Deval test is able to affect the aggregate texture within the 180-minute period. Therefore, the Micro-Deval is considered a good mechanism to polish aggregates, and it requires less time and effort than the polishing used in the Accelerated Polishing Test. A summary of texture before and after the Micro-Deval is shown in Table 4.2. It can be seen that the aggregates differed significantly in the amount of texture lost due to polishing. Also, initial texture cannot be relied on alone to characterize aggregates. As shown in Table 4.3, aggregates rank differently based on texture before polishing, texture after polishing, and percent loss of texture. The use of BMD texture as the ranking criterion would lead to misleading results. For example, aggregate 4 started with very high texture, but ended up ranked number two after polishing. The use of percent loss of texture can also be misleading. Aggregate 4 ranked sixth using this criterion, while it had the highest BMD texture and the second highest AMD texture. Also, aggregate 1 ranked as the best using the percent loss of texture, and it had the second lowest initial texture and ranked third AMD texture.

Table 4.2. Aggregate Texture, Before and After Micro-Deval

| Aggregate # | BMD Texture | AMD Texture | %Loss of Texture |
|--------------------|--------------------|--------------------|-------------------------|
| 1 | 114.10 | 105.67 | 7.39 |
| 2 | 192.77 | 93.37 | 51.57 |
| 3 | 79.70 | 41.03 | 48.53 |
| 4 | 310.58 | 150.20 | 51.64 |
| 5 | 163.18 | 97.36 | 40.34 |
| 6 | 220.93 | 183.35 | 17.01 |

Table 4.3. Ranking of the Aggregates Using Three Different Criteria

| Rank | BMD Texture Criteria | AMD Texture Criteria | % Loss of Texture Criteria |
|----------------------------|-----------------------------|-----------------------------|-----------------------------------|
| 1 (Highest Texture) | 4 (310.58) | 6 (183.35) | 1 (7.39) |
| 2 | 6 (220.93) | 4 (150.20) | 6 (17.01) |
| 3 | 2 (192.77) | 1 (105.67) | 5 (40.34) |
| 4 | 5 (163.18) | 5 (97.36) | 3 (48.53) |
| 5 | 1 (114.1) | 2 (93.37) | 2 (51.57) |
| 6 (Lowest Texture) | 3 (79.70) | 3 (41.03) | 4 (51.64) |

The results discussed above prompted the development of an analytical method that can capture initial texture, final texture, and the change in texture. Two function were used to fit the data,

$$Texture(t) = a + b \times e^{-ct} \quad (2)$$

$$Texture(t) = a - \frac{t}{b + c \times t} \quad (3)$$

where

Texture(t) = aggregate texture as function of time

t = time in minutes

a, and b = parameters representing initial and final texture.

c = parameter representing rate of texture loss

Eq. 3 was used by Kandhal et al. (1993). Table 4.4 shows the fitting parameters using the first function (Eq. 2), while Table 4.5 shows fitting parameters for the second function (Eq. 3)

Table 4.4. Equation 2 Fitted Parameters

| Aggregate | a | b | c |
|------------------|----------|----------|----------|
| 1 | 98.98 | 15.12 | 1.59999 |
| 2 | 61.85 | 139.52 | 0.01445 |
| 3 | 34.12 | 41.43 | 0.01853 |
| 4 | 179.95 | 126.11 | 0.03061 |
| 5 | -790.76 | 960.99 | 0.00051 |
| 6 | 164.76 | 52.19 | 0.00775 |

Table 4.5. Equation 3 Fitted Parameters

| Aggregate | a | b | c |
|------------------|----------|-----------|------------|
| 1 | 100.87 | 1061649.6 | 53687091.2 |
| 2 | 200.71 | 0.489 | 0.00447 |
| 3 | 79.81 | 0.470 | 0.02282 |
| 4 | 308.75 | 0.191 | 0.00616 |
| 5 | 169.14 | 2.395 | -0.00277 |
| 6 | 217.58 | 2.103 | 0.01416 |

Figs. 4.10, 4.11, 4.12, 4.13, 4.14, and 4.15 shows the two fitting functions for the aggregates 1, 2, 3, 4, 5, and 6, respectively. Only aggregate 1 did not fit well with the two functions. As discussed previously aggregate 1 did not lose its texture with time in the Micro-Deval. For the other five aggregates the two function fitted the data points very well. All aggregates tended to reach a constant texture value, except for aggregate 5 which continued to lose texture with the testing time.

Fig. 4.10. Equations 2 and 3 fitting plots for crushed gravel

Fig. 4.11. Equations 2 and 3 fitting plots for hard crushed limestone

Fig. 4.12. Equations 2 and 3 fitting plots for soft crushed limestone

Fig. 4.13. Equations 2 and 3 fitting plots for traprock

Fig. 4.14. Equations 2 and 3 fitting plots for quartzite

Fig. 4.15. Equations 2 and 3 fitting plots for crushed granite

Fig. 4.16 shows a comparison between the Micro-Deval weight loss and the texture loss. It is interesting to note that there is no unique relationship for all aggregates. This finding indicates that weight loss cannot be correlated to texture loss using the same relationship for all aggregates. Fig. 4.17 presents the plot of only aggregates 2 and 6, and it is obvious how the magnitude of weight loss is not an indicator of texture loss, for example at 8 percent weight loss aggregate 6 lost around 15 percent of its texture, while aggregate 2 lost 30 percent of texture.

Fig. 4.16. Comparison Between Weight Loss and Texture Loss (All Aggregates)

Fig. 4.17. Comparison Between Weight Loss and Texture Loss (Aggregates 2 and 6)

Analysis of Accelerated Polish Test

The accelerated polish test results using Tex-438-A were grouped into different ranges as shown in Table 4.6. As given in Table 4.6 and Fig. 4.18, the results were within a very small range, where 61 percent of the data were between a PV of 28 and 32; that is a range of 4 PV. Kandhal et al. (1993) reported similar results; they reported that 59 percent of limestone aggregates are between the values of 28 and 32, while 75 percent of gravel aggregates results are in the same range. This means that distinguishing between aggregates using this method is very difficult. The other drawback of this test, which is presented in the literature review is that this test result (PV) is a function of many factors other than texture. The relationship shown in Fig. 4.19 between PVs and aggregate texture shows that there is no correlation between these two parameters.

Table 4.6. PV Frequency Percentages Distribution

| Range | Frequency | Percentage (%) |
|-------------------|-----------|----------------|
| $24 < PV \leq 28$ | 7 | 21 |
| $28 < PV \leq 32$ | 20 | 61 |
| $32 < PV \leq 36$ | 1 | 3 |
| $36 < PV \leq 40$ | 4 | 12 |
| $40 < PV \leq 44$ | 0 | 0 |
| $44 < PV \leq 48$ | 0 | 0 |
| $48 < PV \leq 52$ | 1 | 3 |
| Total | 33 | 100 |

A METHODOLOGY FOR MEASURING AGGREGATE RESISTANCE TO ABRASION AND BREAKAGE

Aggregate abrasion is defined in this study as the aggregate loss of its surface angularity.

In the Micro-Deval test, aggregates are subjected to both abrasion and breakage, and both of these mechanisms are associated with weight loss. Visual inspection of aggregates after Micro-Deval testing indicated that some of the aggregates were only abraded, while others experienced breakage with minimal change in their surface angularity. In this section, a procedure is developed to distinguish between aggregate breakage and abrasion. This procedure consists of three steps: (1) measure aggregate initial angularity, (2) test the aggregate in the Micro-Deval, and (3) measure its angularity and weight loss after the Micro-Deval.

A comparison between angularity before and after the Micro-Deval is shown in Fig. 4.20. This plot is a good source of information on how angularity changes as a result of abrasion in the Micro-Deval. Fig. 4.20 also shows that AIMS is capable of detecting changes in angularity, as all aggregates plot to the right of the equality line indicating loss of angularity or abrasion.

Fig. 4.20. Comparing Aggregate Angularity Before and After Micro-Deval

The percent change in angularity is plotted against Micro-Deval weight loss (aggregate passing sieve #16) in Fig. 4.21 to distinguish between abrasion and breakage. Aggregates with high weight loss but low angularity loss were those that experienced high breakage and low abrasion. Aggregates that had high angularity loss and high

weight loss were the ones that encountered both high abrasion and high breakage. On the other hand, low values of weight loss and angularity loss were associated with low abrasion and breakage. Finally, aggregates with high angularity loss but low weight loss were the ones that had high abrasion and low breakage.

Fig. 4.21. Percent Weight Loss (#16) against Percent Angularity Change

It can be argued that the use of Micro-Deval weight loss is not a good indicator for breakage as it only includes the loss of aggregates smaller than the #16 sieve. Therefore, it was decided to explore whether the use of weight loss of particles passing the #4 sieve would change the relationship in Fig. 4.21. It was found that excellent correlation exists between loss of aggregates passing the #16 sieve and aggregates passing the #4 sieve

(Fig. 4.22). Of course, the weight of aggregates passing the #4 sieve would be expected to be larger than the weight passing the #16 sieve, and this would shift the angularity loss versus weight loss relationship in Fig. 4.23 compared with Fig. 4.21. It is recommended to use loss of weight passing sieve #16 in accordance to the current Micro-Deval test procedure, and to avoid adding an unnecessary extra step to the test.

Fig. 4.22. Correlation Between #4 %Weight Loss and #16 %Weight Loss

Fig. 4.23. Percent Weight Loss (#4) against Percent Angularity Change

SUMMARY

This chapter included the development of a methodology for measuring aggregate resistance to polishing. The methodology relies on measuring aggregate texture using AIMS before and after polishing in the Micro-Deval.

The results indicated the capability of the Micro-Deval to polish aggregates until they reach their final texture condition. An analytical procedure was also developed to analyze the loss of texture as a function of polishing time. This procedure allows for estimating the initial texture, the rate of texture loss, and the final texture. These factors should be considered when aggregate characteristics are related to pavement frictional or skid resistance.

A new methodology was also developed for measuring aggregate resistance to abrasion and breakage. The Micro-Deval was found to cause both aggregate abrasion and breakage. Plotting percent change in angularity, which is a measure of abrasion versus weight loss, made it possible to distinguish between aggregate abrasion and degradation. It was also found that weight loss defined as weight passing sieve #16 is correlated with weight loss defined as weight passing the #4 sieve. The use of weight loss passing the #16 sieve is recommended to avoid adding an extra step to the test.

The procedure is useful if one is interested in determining aggregate resistance to abrasion and/or breakage. This procedure will be valuable for determining whether aggregates used during the mix design would be different than those used in the field due to abrasion and/or breakage in the plant and under compaction. Also, the procedure would be useful to select aggregates that can be used in mixes that rely heavily on stone-to-stone contacts. If one is interested in the effect of angularity on performance, then the initial angularity should also be taken into consideration. Some aggregates can have high loss of angularity, but their initial angularity is high enough to warrant acceptable remaining angularity for performance. However, the high loss of angularity of these aggregates remains a concern for changes in mix design irrespective of their contribution to mix performance.

CHAPTER V

CONCLUSIONS AND RECOMMENDATIONS

CONCLUSIONS

This study deals with the development of new methods for the evaluation of aggregate resistance to polishing, abrasion, and breakage. Aggregate resistance to polishing is an important property that affects asphalt pavement frictional resistance or skid resistance. Aggregate resistance to abrasion and breakage is a property that influences changes in aggregate characteristics during production and compaction. Also, aggregates need to resist abrasion and breakage due to the high contact stresses in mixes that rely on stone-to-stone contacts.

The review of literature indicates that current methods used for assessment of aggregate polishing have several drawbacks. These methods are time-consuming in preparing and polishing the samples, and the results of some of these methods are functions of other factors besides aggregate texture. For example, coupon curvature and aggregate size affect the results of the British wheel/pendulum method.

In terms of abrasion and breakage resistance, there is enough evidence in the literature that the Micro-Deval test can be used for measuring aggregate resistance to both abrasion and breakage. However, there is a concern that aggregate weight loss could be attributed to either abrasion or breakage.

The new methods for measuring aggregate characteristics are based on the Micro-Deval and Aggregate Imaging System (AIMS) results. Therefore, it was

necessary to evaluate the variability in these two test methods. Angularity and texture measurements from two AIMS units were statistically not different. Also, texture measurements on polishing coupons measured by two AIMS units were not statistically different. Excellent correlations were found between the results from the two AIMS units. Micro-Deval measurements conducted using two different machines were also analyzed, and the results from the two machines were not statistically different.

The new methodology for measuring aggregate resistance to polishing relies on measuring aggregate texture using AIMS before and after polishing in the Micro-Deval. Aggregate loss of texture as a function of polishing time can be analyzed using an analytical procedure that allows estimating initial texture, rate of texture loss, and the final texture. Such factors are important when aggregates' characteristics are related to pavement skid resistance. This new method is rapid and accurate in measuring aggregate resistance to polishing.

A methodology was developed for measuring aggregate resistance to abrasion and breakage. The methodology relies on measuring aggregate angularity using AIMS before and after abrasion in the Micro-Deval, in addition to the weight loss percent in the Micro-Deval. The Micro-Deval was found to cause both aggregate abrasion and breakage. Plotting percent change in angularity (abrasion measure) versus weight loss made it possible to distinguish between aggregate abrasion and breakage. The new methodology for measuring aggregate resistance to abrasion and breakage can be used in the selection of aggregates for mixes that rely on stone-to-stone contacts, and in the

assessment of changes in aggregates characteristics during mix production and compaction.

AIMS and Micro-Deval tests provide rapid and accurate methods for assessing aggregate resistance to polishing, abrasion, and breakage. These procedures require reasonable time and training, and are expected to replace the methods currently in practice.

RECOMMENDATIONS

It is recommended to study the reproducibility of AIMS measurements using more than two units. Also, testing should include the same exact particles in the same order to conduct paired statistical analysis.

It is recommended to implement the new methodologies for measuring aggregate resistance to polishing, abrasion, and breakage in routine operations of state highway agencies. There is a need to link the measured aggregate characteristics to asphalt pavement frictional resistance, and abrasion and breakage in plant operations and under compaction.
